

Data Analysis

For **AT-TPC** Test Chamber
Hongwei WANG

Read data from the binary file

1 Data format:

The following drawing summarizes the data file format:

2 Byte swap:

WARNING: All binary numbers are in “Big Endian format”, also called the “network byte order” meaning that *the most significant bytes come first*. On Intel platforms, the numbers are in “Little Endian” format so that when you read a Big Endian 4-byte integer from the data file, *you have to swap the bytes*. This is done using the `ntohl()` and `ntohs()` standard functions respectively for 32-bit and 16-bits integers (The meaning of the function names are ‘network to host long’ and ‘network to host short’). To use these functions you have to include `<arpa/inet.h>` on Linux/Unix platforms and `<winsock2.h>` on Windows.

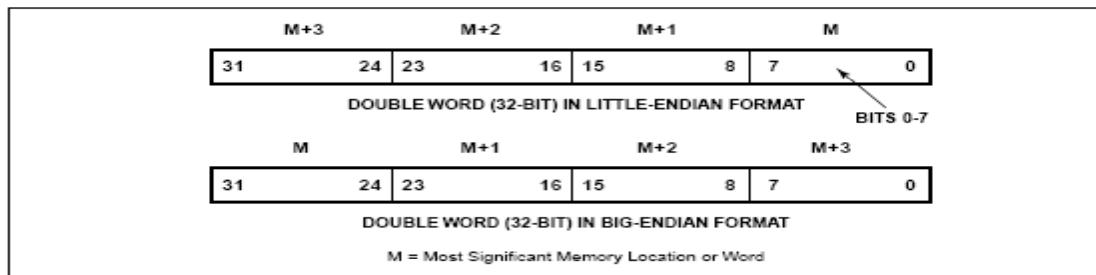

Figure 1. Big Endian vs. Little Endian Memory Formatting

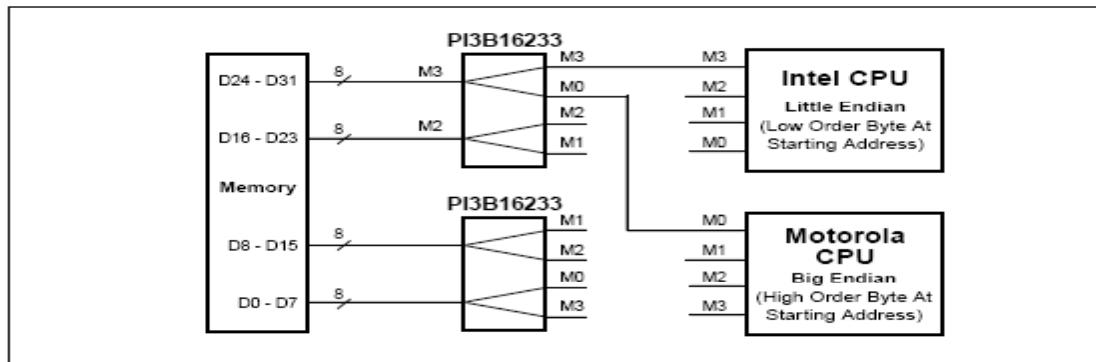

Figure 2. Converting Between Big Endian and Little Endian

3 Unsigned integer: (4 byte), in Fortran, no such data type, the last bit(15) is sign bits .

We solved these problems by use **the ishiftc, ibits and mvbits** intrinsic functions in Visual Fortran 6.5.

But we also find they have different definition in **gfortran (gcc)** and **Visual Fortran**, especially for **open . ?**

Raw data

Event Num

ASCII Format

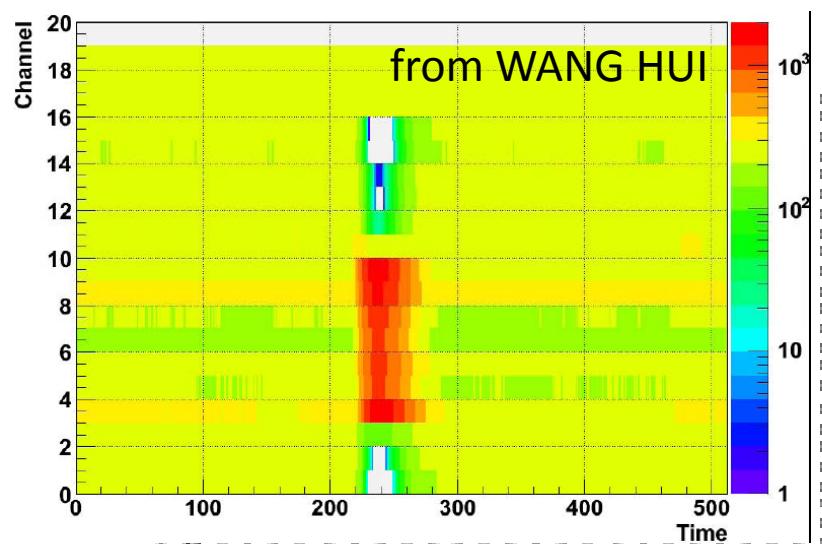

Pad Num

Pad Number 1-79

Background
spectrum

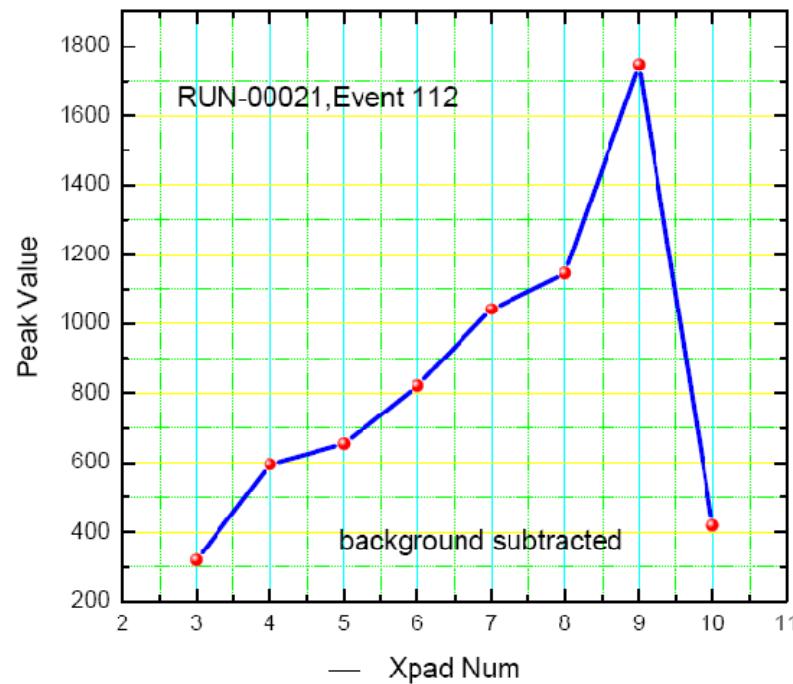

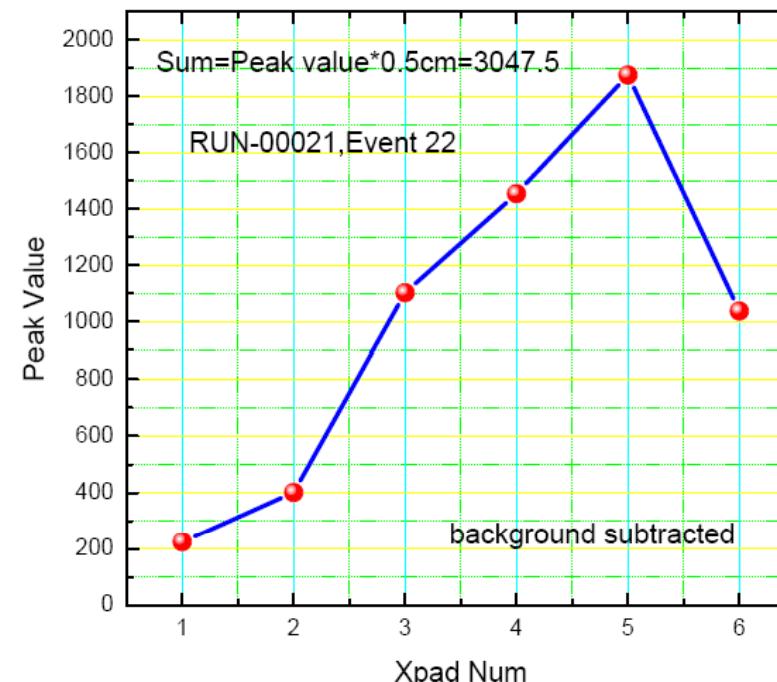

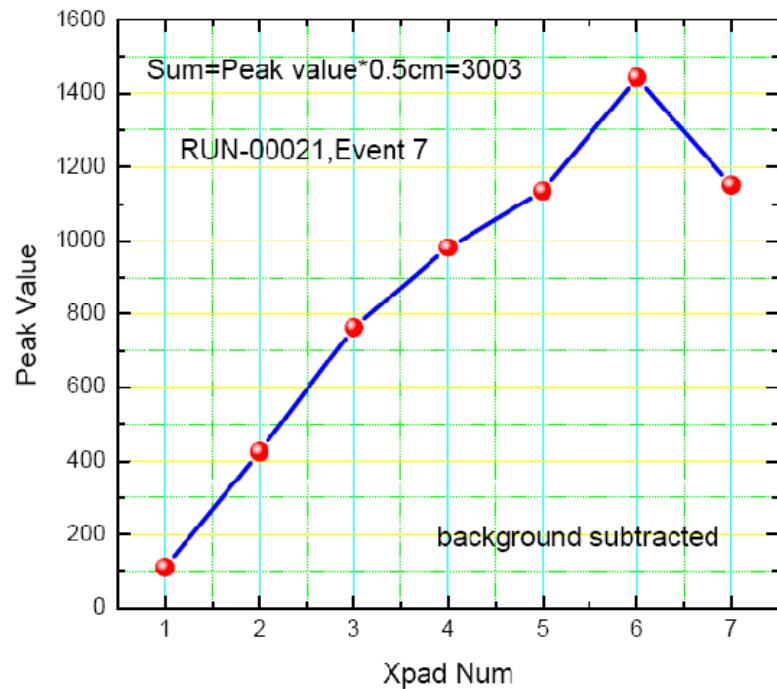

Event data

After background subtracted, we can see the event data, here we only show the time scale 220 -280 channel.

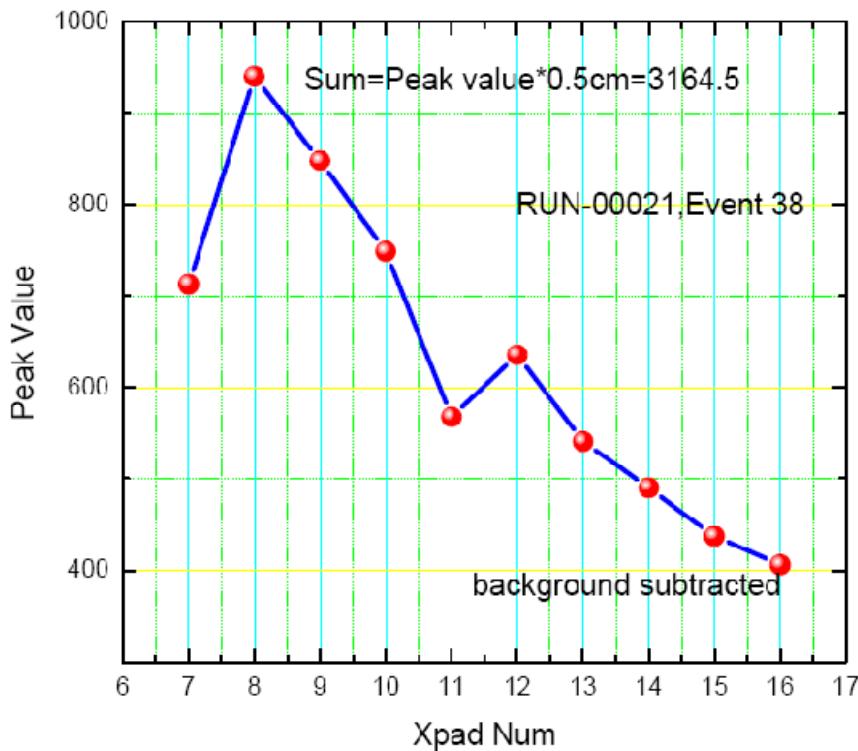

Then we will look for the maximum value of each pad in time channel, and get such figures.

Bragg Curve

They are **good Events** we defined

We call this maximum value as Qi

They are **bad Events** we defined, and it also include some events have one and two pad triggered.

CHI2 Definition

definition:

$$\chi^2 = \sum \frac{(Q_i - T_i \times Norm)^2}{\sigma^2}$$

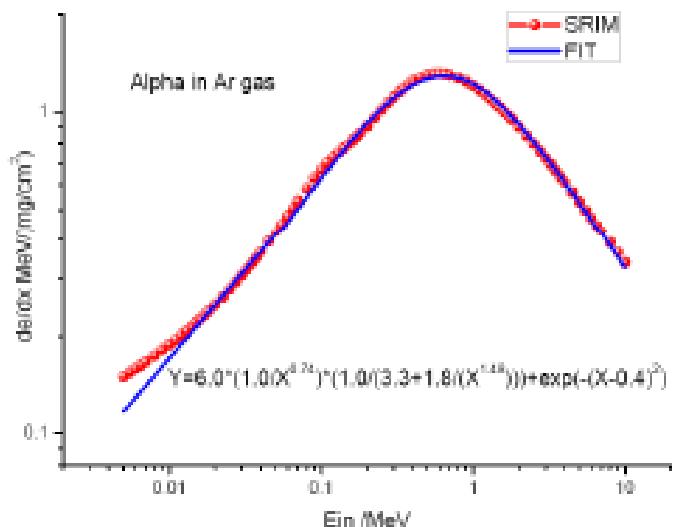

$$Norm = \frac{\sum_{i=\max-1}^{\max+2} Q_i}{\sum_{i=\max-1}^{\max+2} T_i}$$

$$\sigma = N - \bar{N} \quad (N : background\ data, \bar{N} : Average\ Value)$$

We only use last three or four point for calculation .

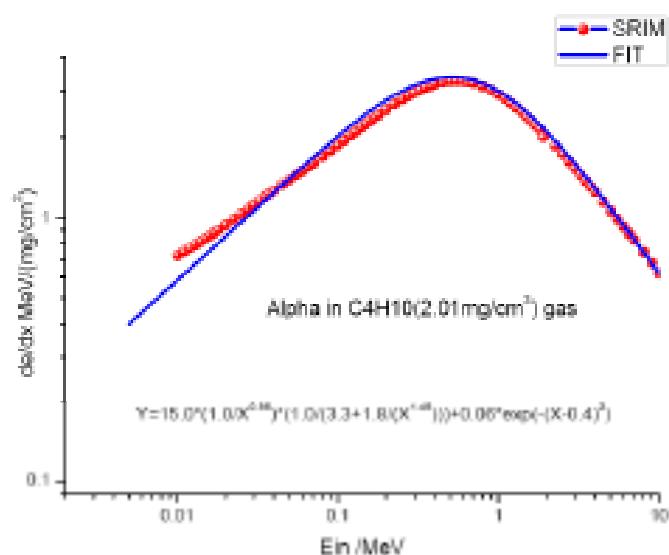

Because other point have a very lower energy loss,
So these data point have much large fluctuation

Theoretical calculation stopping power de/dx curve

Stopping power calculation by SRIM
In Ar(90%) and Isobutene(C₄H₁₀,10%)
gas.

Analytical formula be used in our
analysis program.

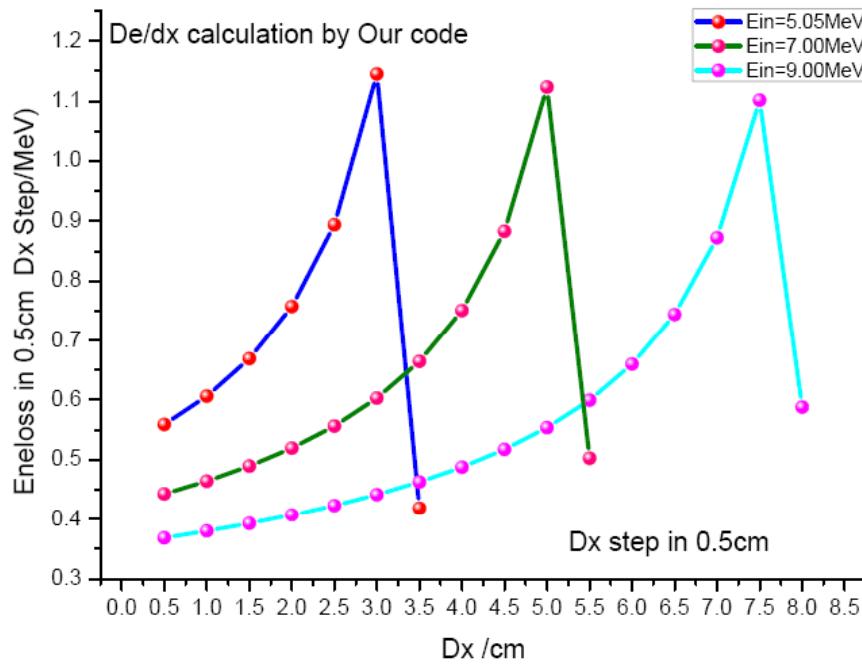

Ar : Density= Gas pressure*40*90%/22400

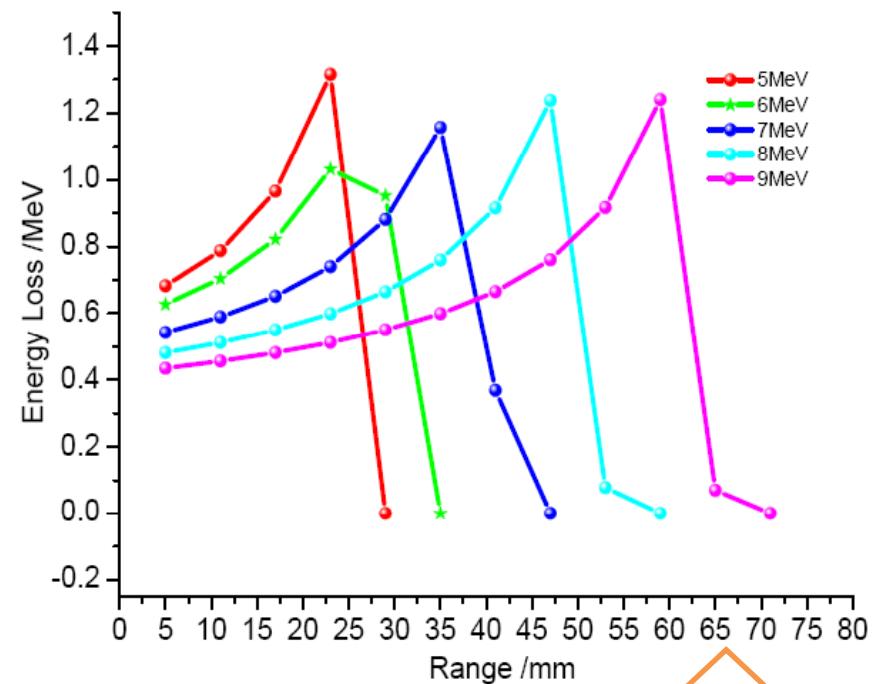

C4H10 : Density= Gas pressure*40*10%/22400

Energy loss in Dx=0.5 cm step (pad size)

Total Energy be verified from 5 MeV to 9 MeV

Theoretical Bragg curve

We call this value as Ti

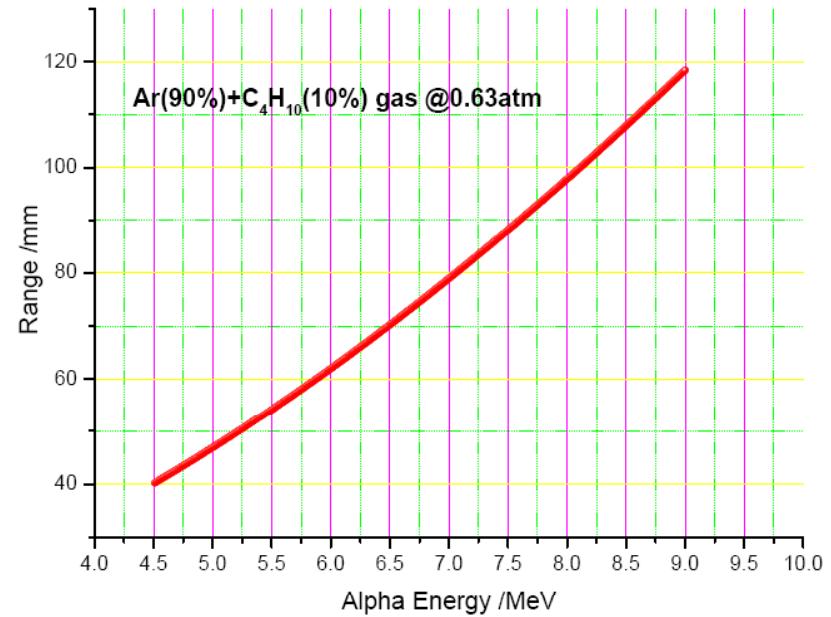

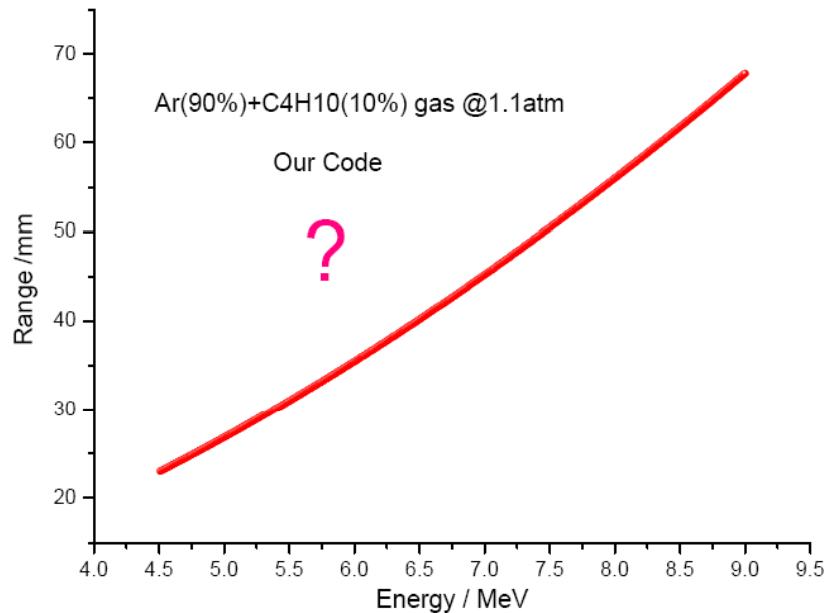

Here, We think about the 1.0 cm distance between Alpha source and Collimator

Then 0.5 cm Pad size and 0.1 cm Gap between Pad

We Compare these Theoretical Value with Exp data by pad num

Energy - Range Curve calculation by our program

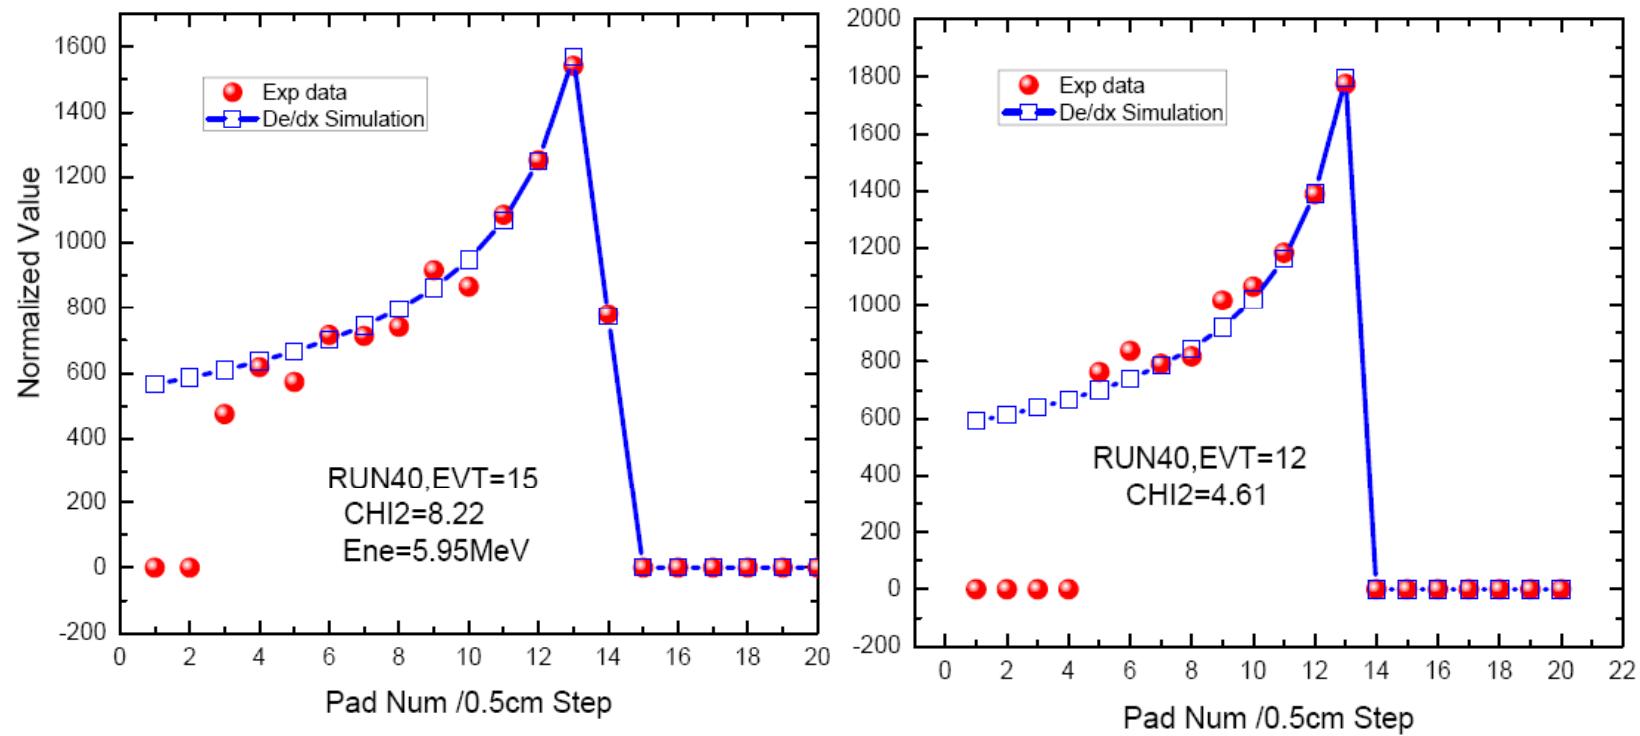

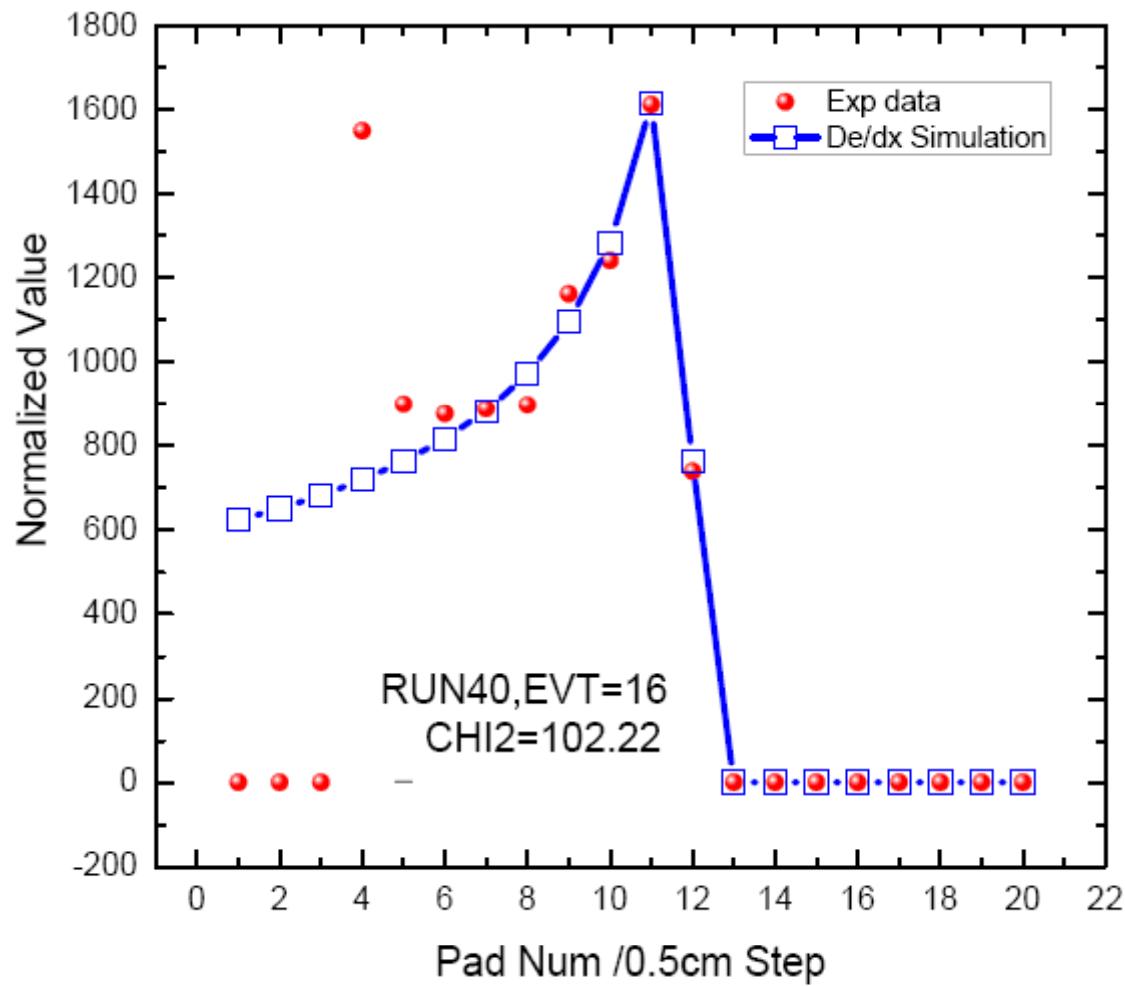

Alpha standard source

228Th: **5.520** (100%), **5.789**(100%), **6.208**(36%), **6.404**(100%), **6.906**(100%), and **8.955**(64%)

241Am: **5.389**(1.3%), **5.443**(12.8%), **5.486**(85.2%) **5.513**(0.12%), **5.545**(0.35%)

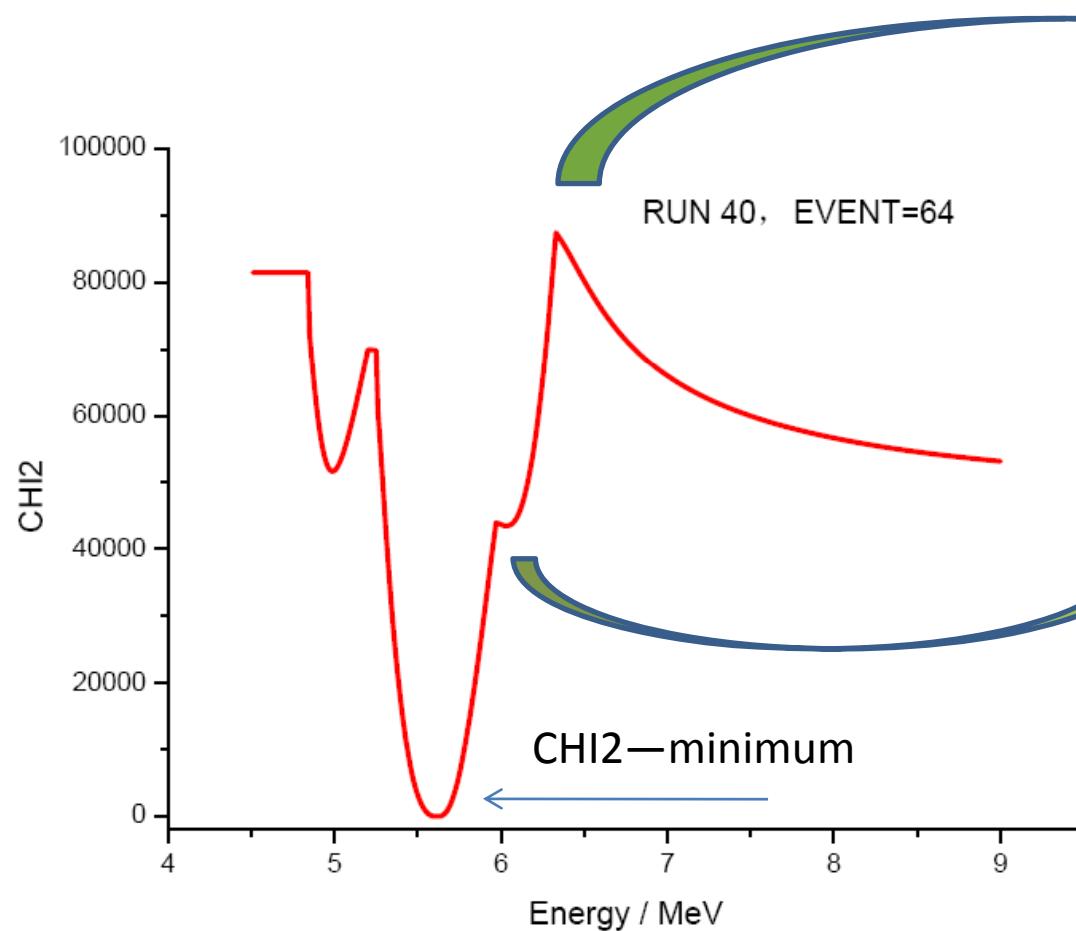

Compare with the Exp data(after normalized)

So you will see if we calculate other tail point,
the CHI2 will be a more large value

Energy loss in pad

We search for minimum CHI2 value for possible Alpha Energy

Good Event Selection

Total triggered pad num ≥ 3

Brag peak pad ≥ 5

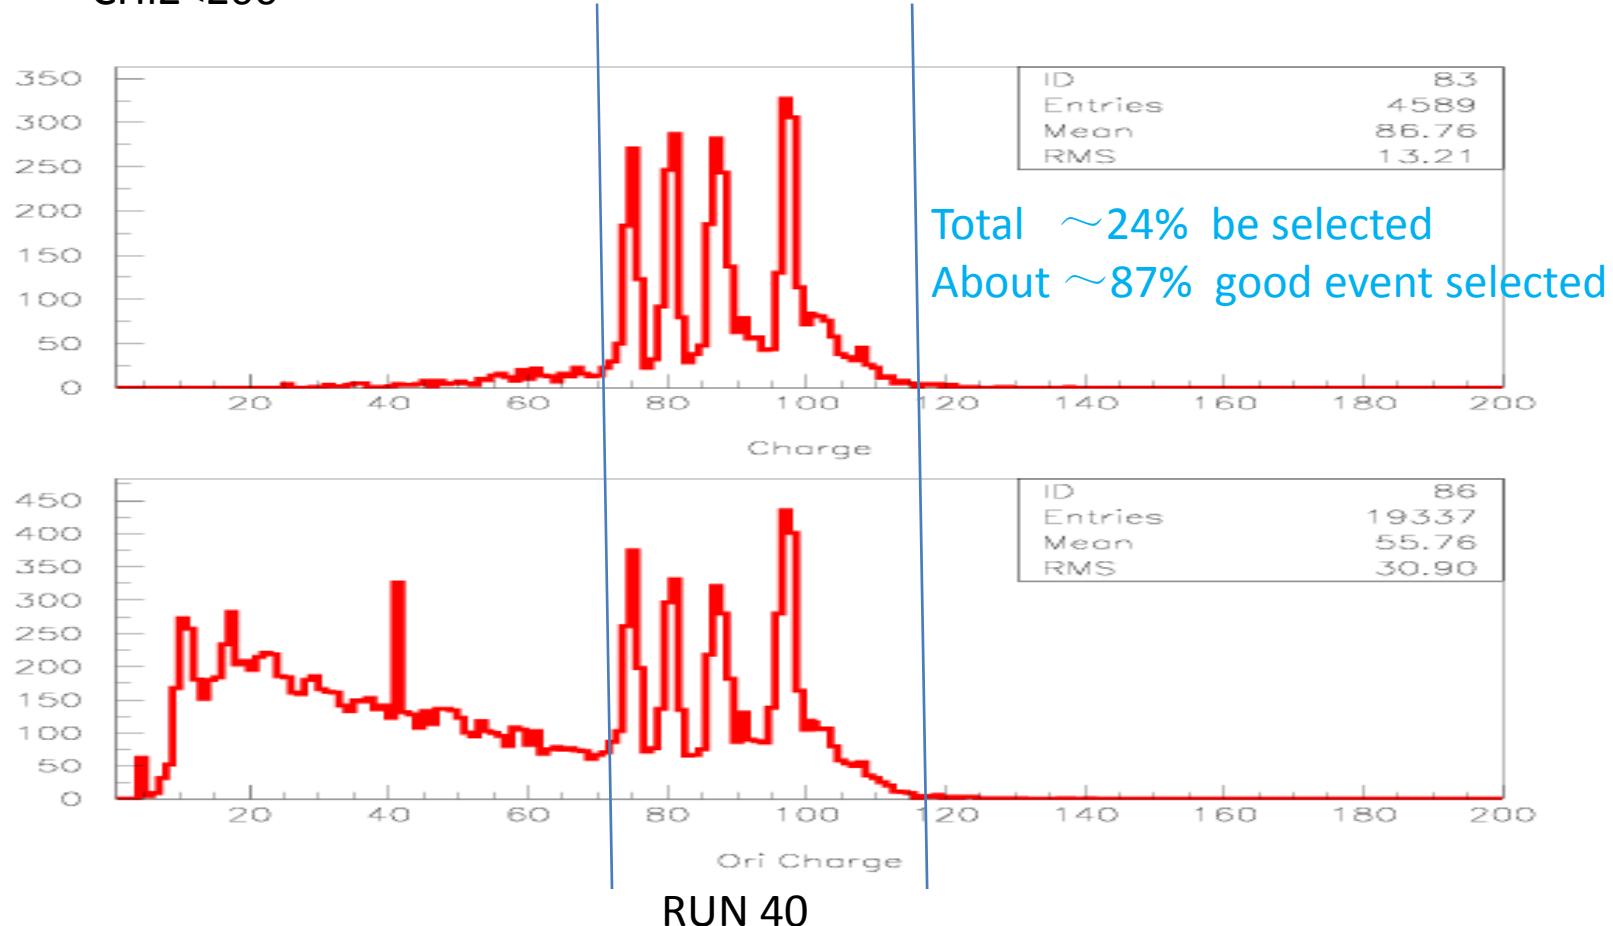

Pad(max) ≥ 900

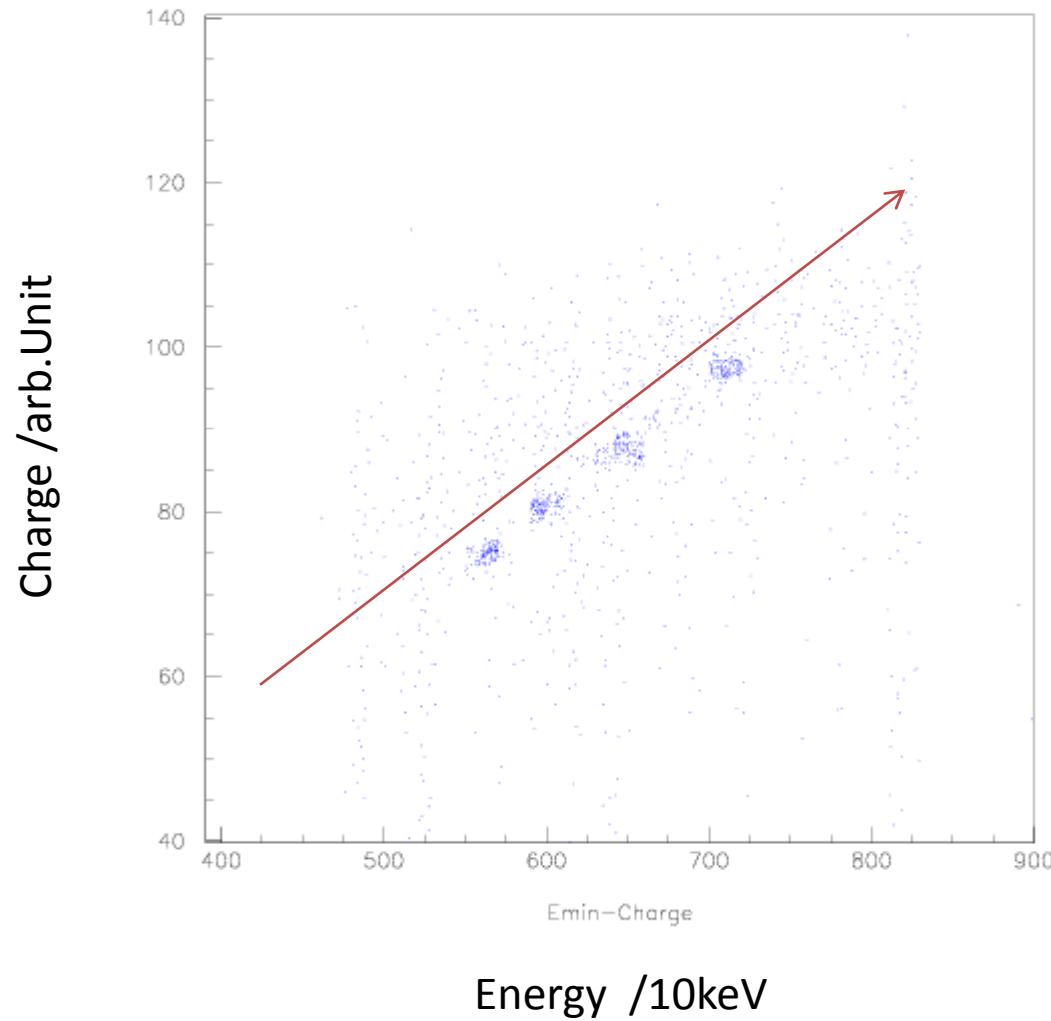

Pad(max+3)=0

CHi2 <200

Low gas
Pressure

Charge to Energy Transform

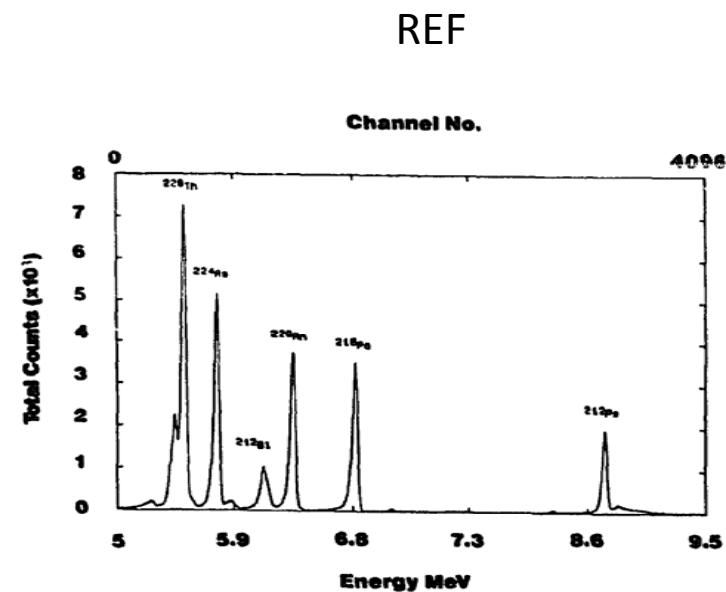

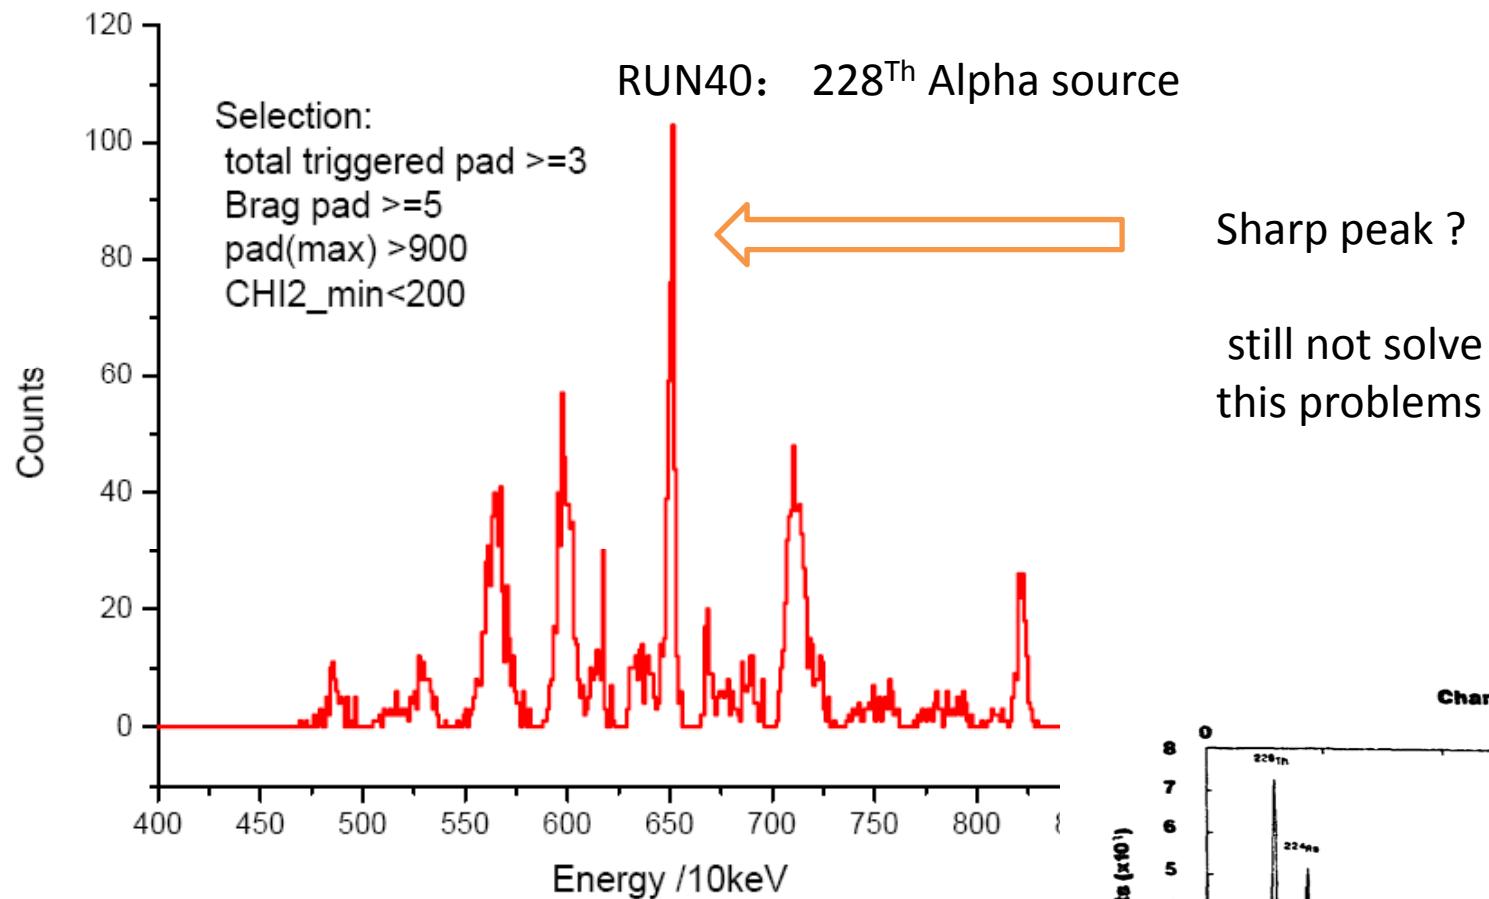

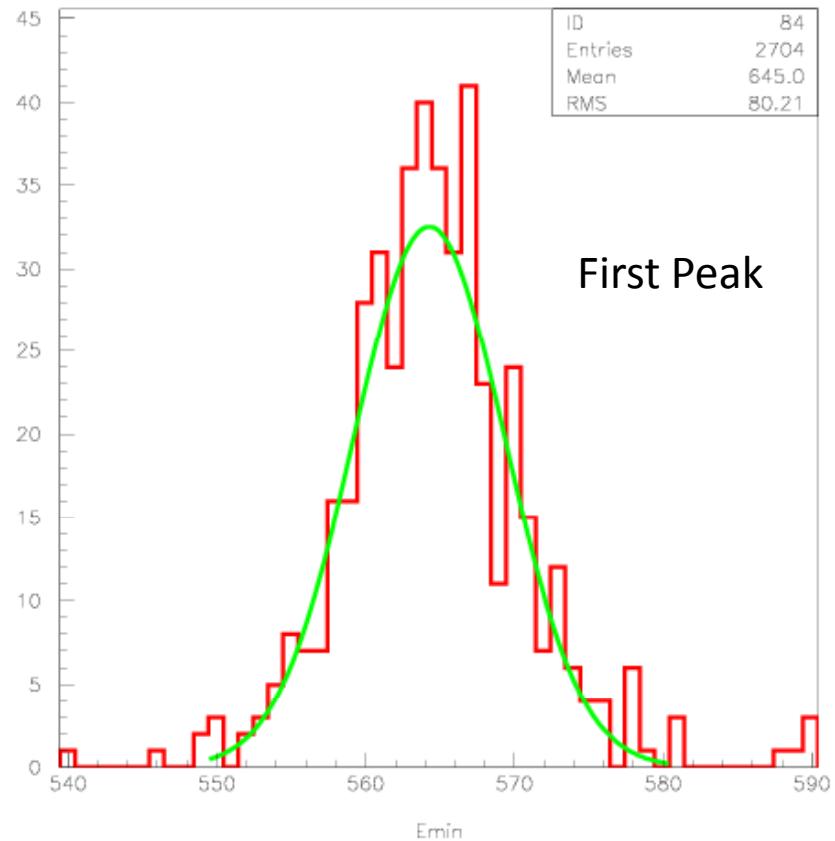

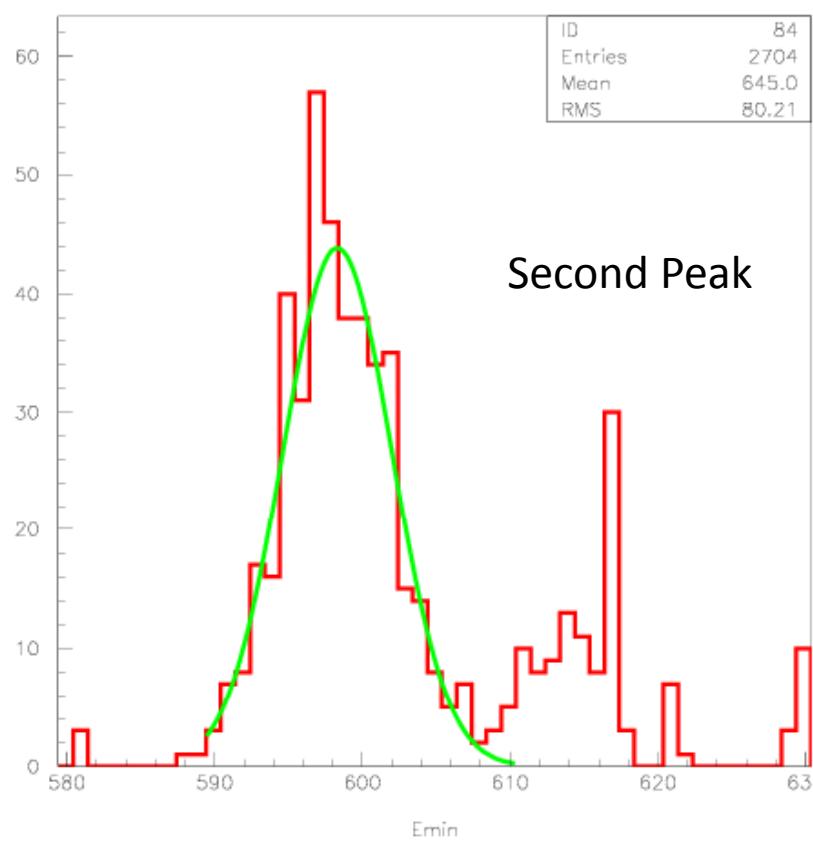

Fig. 2. Spectrum recorded using an ion-implanted Si detector of ^{228}Th and daughter activity.

Sigma=50.85

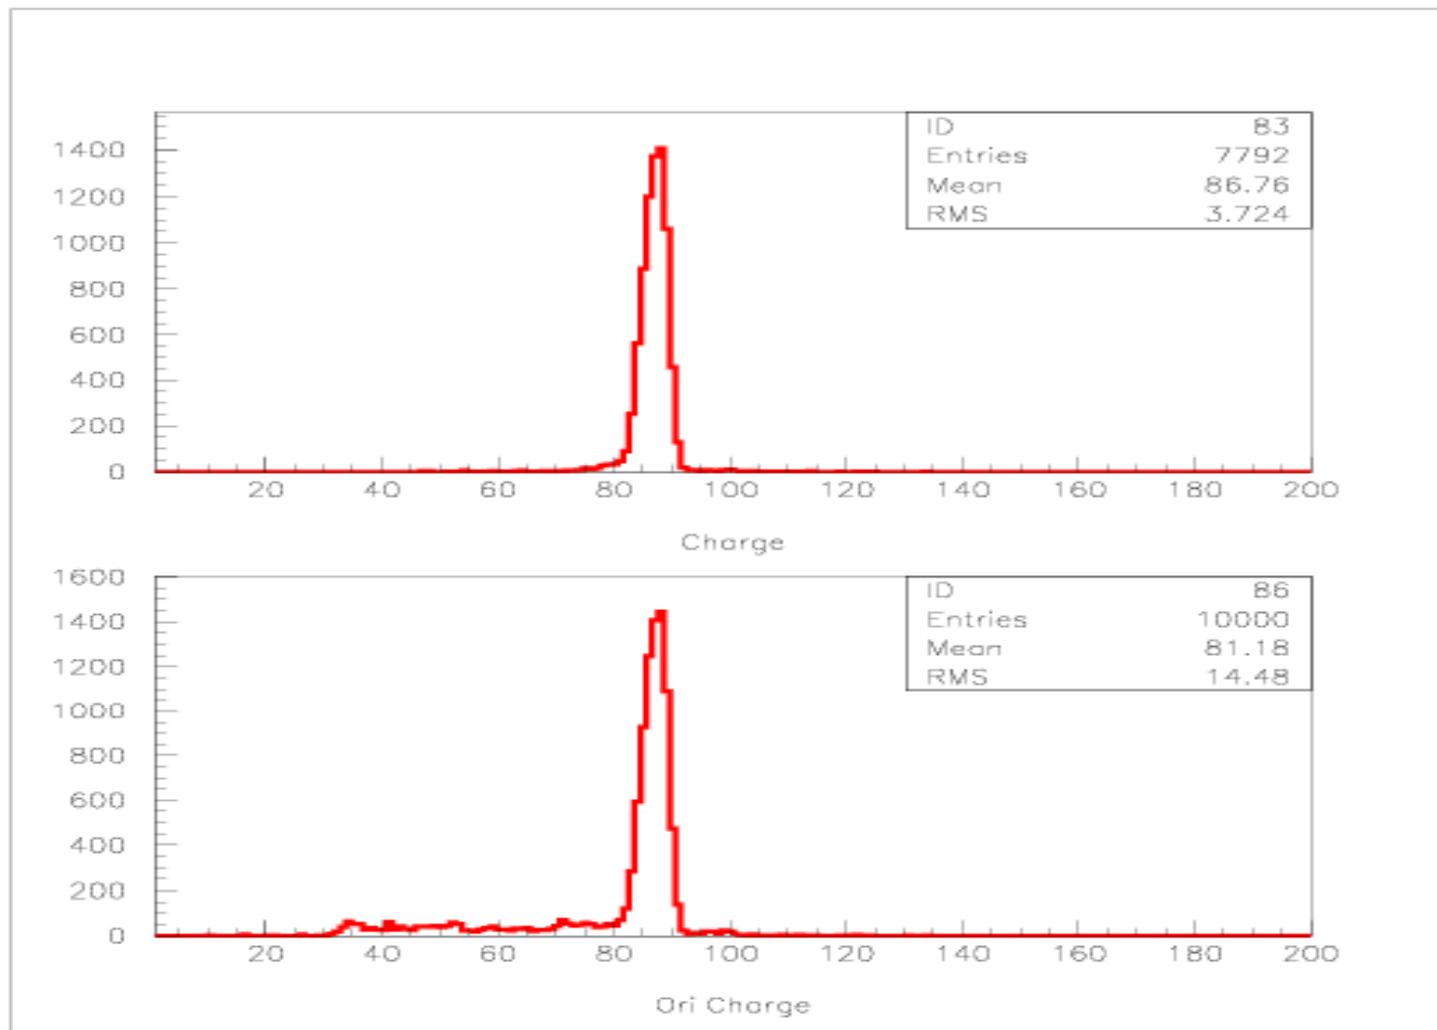

Sigma=37.09

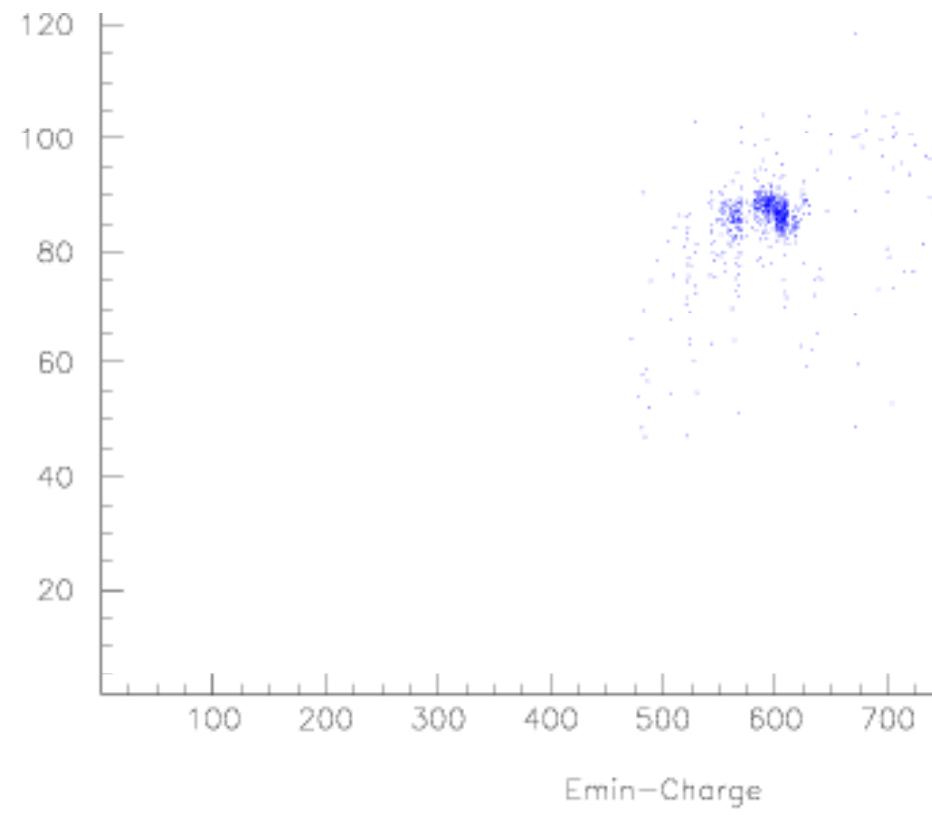

So FMHW $\sim 70 - 150$ keV

RUN47: 241Am Alpha Source

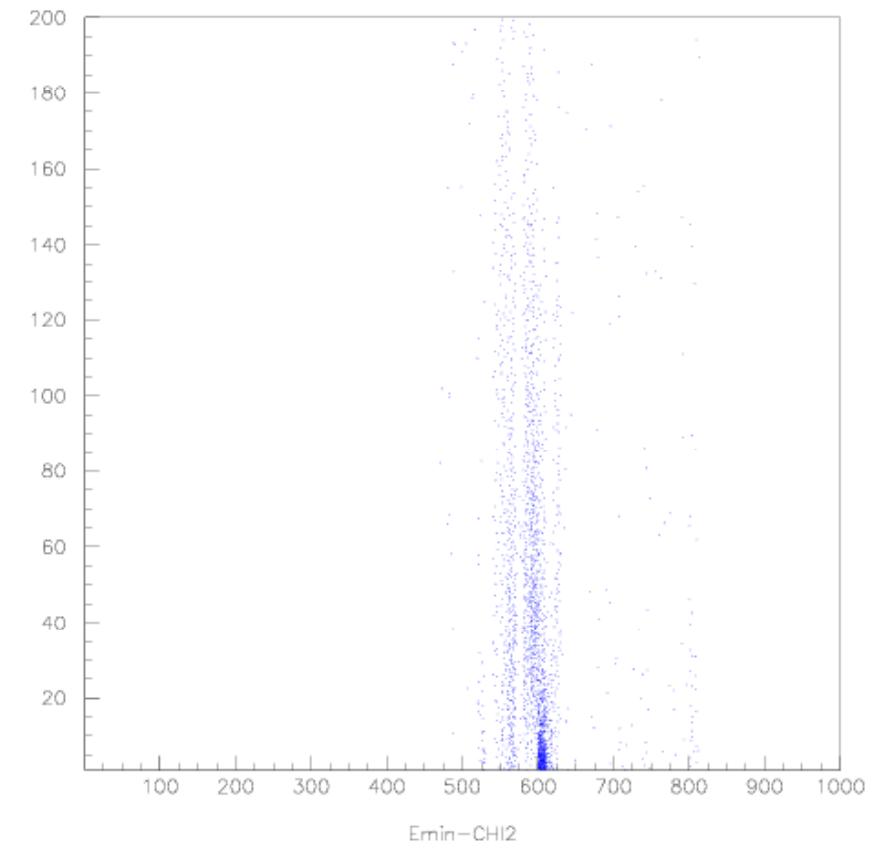

~ 77% be selected

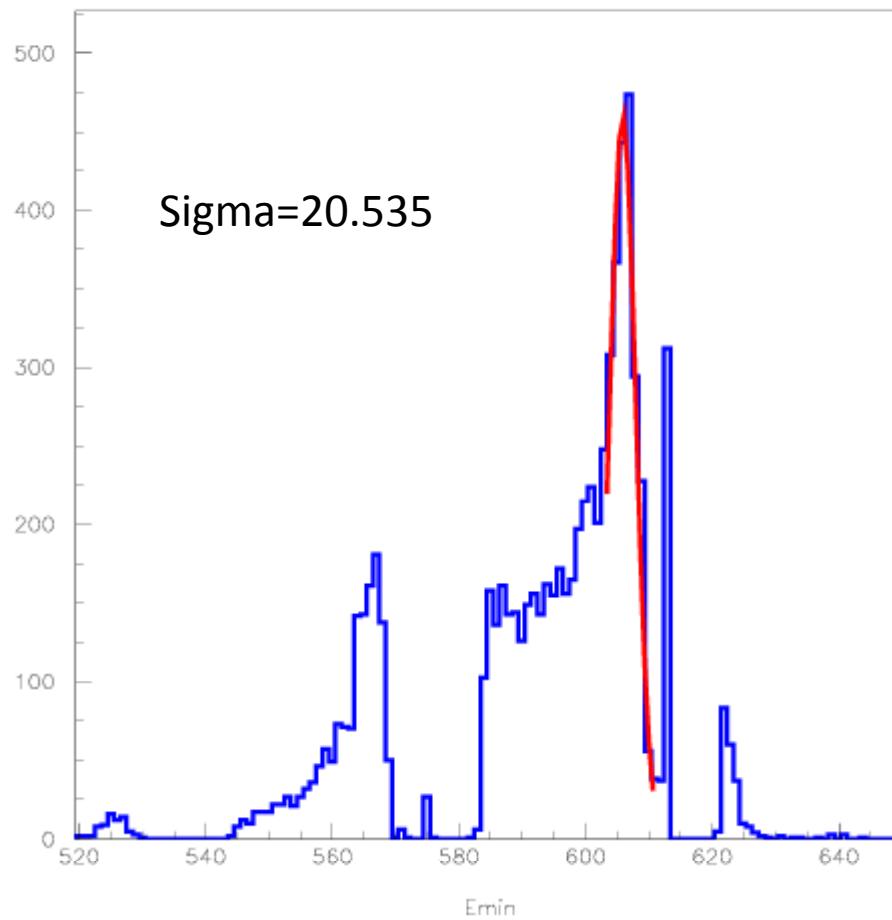

RUN 47

Energy-Charge spectrum

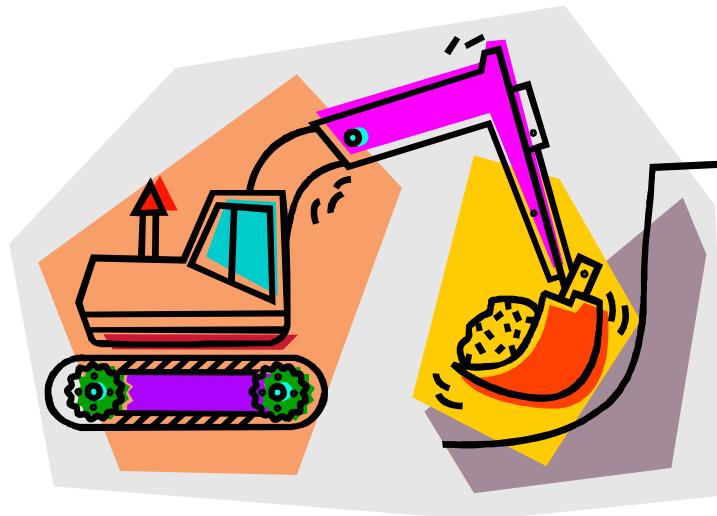

Energy-CHI2 spectrum

So FWHM \sim 50 keV

Thanks for your attention

More work need to do
